## Notes and solutions

Alex Elzenaar

March 21, 2019

*The first analogy that came to my mind is of immersing the nut in some softening liquid, and why not simply water? From time to time you rub so the liquid penetrates better, and otherwise you let time pass. The shell becomes more flexible through weeks and months—when the time is ripe, hand pressure is enough, the shell opens like a perfectly ripened avocado! A different image came to me a few weeks ago. The unknown thing to be known appeared to me as some stretch of earth or hard marl, resisting penetration... the sea advances insensibly in silence, nothing seems to happen, nothing moves, the water is so far off you hardly hear it... yet it finally surrounds the resistant substance.*

(Grothendieck)

## Preface

This is a set of notes and outlines of solutions to the various exercises in the conic section notes.

---

## Notes on Section 2: Basic results

---

### Exercise 1: Polar form.

Show that, if  $X$  is on the directrix of a conic such that  $OX \perp \ell$ , then the polar equation of the conic with respect to this axis and origin  $O$  is

$$\frac{l}{r} = 1 + \varepsilon \cos \theta.$$

Conclude that:

1. Every conic is symmetric with respect to  $OX$ .
2. The ellipse is a closed and bounded curve (i.e. it does not extend towards infinity).
3. The parabola is unbounded, but is connected.
4. The hyperbola consists of two separate branches, each extending to infinity, given by  $-\alpha < \theta < \alpha$  and  $\alpha < \theta < 2\pi - \alpha$  (where  $\alpha = \operatorname{arccos}(-\varepsilon)$ ).

Before answering this, I do need to concede that at this stage we have no good definition for a closed curve, or a connected curve, or for a branch/component of a curve. However, the curves we deal with are so simple that we can say that:

- A closed curve is one which is periodic in  $\theta$ .
- A component/branch of a curve is a set of points on the curve such that (1) each point in the set corresponds to a value of  $\theta$  taken from some open interval  $(a, b)$ ; and (2) each point corresponding to a value of  $\theta$  from the interval is on the curve and has a finite radius.
- A connected curve is one which consists of a single component.

A fairly general and accessible version (restricted to curves in the real plane) can be found in books on multivariate calculus and/or the geometry of curves; see for example the first couple of chapters of do Carmo.<sup>1</sup> However, the ‘proper’ generalisation comes from topology: see for example Munkres (§23–24).

Let us consider the following diagram.

We have the following:  $|OQ| = |OX| - |QX|$ . But  $|OQ| = r \cos \theta$ ,  $|OX| = e/\varepsilon$ , and  $|QX| = |PK|$ ; thus  $r \cos \theta = l/\varepsilon - |PK|$ . But since  $P$  is on the conic,  $\varepsilon = |OP|/|PK| = r/|PK|$ ; hence  $r \cos \theta = l/\varepsilon - r/\varepsilon$  and thus  $l/r = 1 - \varepsilon \cos \theta$ .

---

<sup>1</sup>*Differential geometry of curves and surfaces.*

For (1), we need to check that the graph is symmetric about  $OX$ ; this ray is our polar axis, and so we just need to check that  $(r, \theta)$  is on  $\mathcal{C}$  iff  $(r, -\theta)$  is on the curve. But  $\cos \theta = \cos(-\theta)$ , which is sufficient.

For (2), we need to do some work with inequalities. From the polar equation,  $r = \frac{l}{1+\varepsilon \cos \theta}$ ; so we need to show that this fraction is bounded above (i.e. given any eccentricity  $\varepsilon$  and any length  $l$  then there exists some  $K$  — which depends on  $\varepsilon$  and  $l$  — such that  $|r| < K$  for all possible  $\theta$ ). Let us therefore fix a given eccentricity  $\varepsilon$ . Since the conic is an ellipse, we have  $0 \leq \varepsilon < 1$ .

Since  $\varepsilon$  is real, there exists some positive  $\kappa$  satisfying  $\varepsilon < \kappa < 1$ .<sup>2</sup> Hence we have that  $0 < \varepsilon < \kappa$ , and thus  $-\kappa < -\varepsilon < 0$ ; so  $1 - \kappa < 1 - \varepsilon < 1$ , and thus  $1 + \varepsilon \cos \theta \geq 1 - \varepsilon > 1 - \kappa$ .

From this, we have that  $\frac{1}{1-\varepsilon \cos \theta} < \frac{1}{1-\kappa}$ , and hence  $r < \frac{l}{1-\kappa} < \infty$ .

Further,  $1 + \varepsilon \cos \theta \leq 1 + \varepsilon < 2$ , so  $\frac{1}{2} < \frac{1}{1+\varepsilon \cos \theta}$  and thus  $\frac{l}{2} < r$ . Combining our two  $r$ -involving inequalities, we obtain

$$\frac{l}{2} < r < \frac{l}{1-\kappa};$$

so  $r$  (and thus the curve) is bounded. The closedness of the curve is trivial, since  $r$  is periodic (with period dividing  $2\pi$ ).

For (3), we need to show the parabola  $r = \frac{l}{1+\cos \theta}$  is unbounded (note  $\varepsilon = 1$ ). But this is clearly true, for if  $\theta \rightarrow \pi$  then  $r \rightarrow \infty$ . The parabola is connected, since  $\theta = \pi$  is the only discontinuity, and the curve is periodic otherwise: to see this more clearly, let  $\theta$  vary from  $-\pi$  to  $\pi$ ; the result covers the entire parabola, and is only discontinuous at the endpoints.

Now for (4) we proceed similarly to (3); the curve is periodic with period  $2\pi$ , and  $r \rightarrow \infty$  precisely when  $1 + \varepsilon \cos \theta \rightarrow 0$ ; this latter phenomenon occurs when  $\cos \theta = -1/\varepsilon$ , which is equivalent to  $\sec \theta = -\varepsilon$ . Fix  $\alpha = \operatorname{arcsec}(-\varepsilon)$ ; then all of  $-\alpha$ ,  $\alpha$ , and  $2\pi - \alpha$  satisfy  $\sec(\theta) = -\varepsilon$ , and these three points are the only points in the interval  $[-\alpha, 2\pi - \alpha]$  which satisfy this. If  $\theta$  ranges over this interval we cover the entire curve, and  $r \rightarrow \infty$  only at the endpoints and at  $\theta = \alpha$ . Hence the curve is in two components (since it is continuous everywhere in the interval except these three points), and tends to infinity at the claimed angles.

## Exercise 2: Rectangular form.

By squaring the polar form equation, show that the Cartesian equation for a conic, taking suitable axes and origin, is

$$x^2 + y^2 = (l - \varepsilon x)^2.$$

1. If  $\varepsilon \neq 1$ , and a suitable origin is chosen, show that the conic equation can be written in the form

$$\frac{x^2}{a^2} \pm \frac{y^2}{b^2} = 1$$

for some real numbers  $a$  and  $b$ . The new location of the origin is called the **centre** of the conic. Conclude that:

- (a) Both the ellipse and hyperbola are symmetric across both Cartesian axes.
- (b) For an ellipse, the values  $2a$  and  $2b$  are the lengths of the chords through the origin along the  $x$ - and  $y$ -axes respectively. (The longer of these is called the **major axis**, and the shorter the **minor axis**.)
- (c) The two branches of a hyperbola lie in opposite regions formed by the two lines (**asymptotes**)

$$\left(\frac{x}{a} - \frac{y}{b}\right) \left(\frac{x}{a} + \frac{y}{b}\right) = 0.$$

The value  $2a$  is the length of the transverse axis of the hyperbola and the value  $2b$  is the length of the conjugate axis: the two dimensions of the rectangle whose diagonals are the asymptotes and which is bounded by the hyperbola.

- (d) Further, show that as  $x \rightarrow \pm\infty$ , the branches of the hyperbola tend arbitrarily close to the asymptotes. (Hint: take limits.)

---

<sup>2</sup>We need **completeness** here.

2. If  $\varepsilon = 1$ , show that the conic equation for the parabola can be written in the form

$$y^2 = 2l\left(\frac{1}{2}l - x\right).$$

By reflecting in a suitable vertical line, derive the standard form equation

$$y^2 = 2lx.$$

Given this latter equation, give the coordinates of the focus, and the Cartesian equation of the directrix.

We will pick our origin to be  $O$ , our  $x$ -axis to be the ray in the direction of  $X$  (i.e. the polar axis), and the  $y$ -axis to be the line through  $O$  perpendicular to  $OX$ .

To compute the rectangular form equation take  $r = l - \varepsilon r \cos \theta$ , so  $r^2 = l^2 - 2l\varepsilon r \cos \theta + \varepsilon^2 r^2 \cos^2 \theta$  and then (substituting)  $x^2 + y^2 = l^2 - 2l\varepsilon x + \varepsilon^2 x^2 = (l - \varepsilon x)^2$ .

Assume  $\varepsilon \neq 1$ . Then we collect terms and complete the square:

$$\begin{aligned} x^2 + y^2 = (l - \varepsilon x)^2 &\implies (1 - \varepsilon^2)x^2 + 2l\varepsilon x + y^2 = l^2 \\ &\implies x^2 + \frac{2l\varepsilon}{1 - \varepsilon^2}x + \frac{y^2}{1 - \varepsilon^2} = \frac{l^2}{1 - \varepsilon^2} \\ &\implies \left(x + \frac{l\varepsilon}{1 - \varepsilon^2}\right)^2 - \frac{l^2\varepsilon^2}{(1 - \varepsilon^2)^2} + \frac{y^2}{1 - \varepsilon^2} = \frac{l^2}{1 - \varepsilon^2} \\ &\implies \left(x + \frac{l\varepsilon}{1 - \varepsilon^2}\right)^2 + \frac{y^2}{1 - \varepsilon^2} = \frac{l^2}{(1 - \varepsilon^2)^2}. \end{aligned}$$

*Remark.* I will take some liberties here with regard to choosing  $b$ . In particular, we 'want'  $b$  to be such that  $b^2$  is negative when we have a hyperbola, so we should take  $b = i\beta$  (where  $\beta$  is half the length of the conjugate axis); on the other hand, it is much easier to interpret  $b$  as a length if it is real.

In these notes, I will reverse this notation here and take  $b$  to be the *length* which is half the  $y$ -chord (for both the hyperbola and the ellipse), and  $\beta = ib$  to be the purely imaginary number which has the same modulus. This notation is not standard. ■

Set  $a = \frac{l}{1 - \varepsilon^2}$ , and  $\beta = \sqrt{1 - \varepsilon^2}a$  (where  $\beta$  will be imaginary, in the case of a hyperbola). Then set  $b = |\beta|$ .

Let us make a change of coordinates, sending  $(x, y) \mapsto (x', y') = (x - \varepsilon a)$ ; then our equation becomes

$$(N1) \quad \frac{x'^2}{a^2} \pm \frac{y'^2}{b^2} = 1$$

where the sign  $\pm$  is the same as the sign of  $1 - \varepsilon^2$ ; more precisely, our equation becomes

$$(N2) \quad \frac{x'^2}{a^2} + \frac{y'^2}{\beta^2} = 1$$

but the former is more usual.

Note also that  $l = \frac{\beta^2}{a}$ , in this coordinate system.

If  $(x, y)$  satisfies the equation N2, by the properties of squaring all four sign permutations of  $(\pm x, \pm y)$  satisfy it as well; so the curve is indeed symmetric across both axes.

Now, suppose we have an ellipse; so the sign in the equation is  $+$ . The  $x$ -intercepts of the curve are  $x = \pm a$ , so the chord along the  $x$ -axis has length  $2a$ . By the same reasoning, the  $y$ -intercepts are  $y = \pm b$ , so the  $y$ -axis chord has length  $2b$ .

Now let us consider the case of a hyperbola. We have shifted our origin, and so we need to compute a new polar form, depending on  $a$  and  $b$ . Since  $r^2 = x^2 + y^2$  and  $\tan \theta = \frac{y}{x}$ , we have  $r^2 = x^2(1 + \tan^2 \theta) = x^2 \sec^2 \theta$ . Substituting:

$$1 = \frac{x^2}{a^2} - \frac{y^2}{b^2} = \frac{r^2}{a^2 \sec^2 \theta} - \frac{r^2 \tan^2 \theta}{b^2 \sec^2 \theta} = r^2 \left( \frac{b^2 - a^2 \tan^2 \theta}{a^2 b^2 \sec^2 \theta} \right)$$

and hence

$$(N3) \quad r = \frac{ab|\sec \theta|}{\sqrt{b^2 - a^2 \tan^2 \theta}}$$

is our new polar form (let us call it **central polar form**; in these notes, we will call the polar form from exercise 1 the **focus polar form**).

*Remark.* Let us translate this into the use of imaginary axes, so we can use the same formula for the ellipse as well. We have the following:

$$1 = \frac{x^2}{a^2} + \frac{y^2}{\beta^2} = \frac{r^2}{a^2 \sec^2 \theta} + \frac{r^2 \tan^2 \theta}{\beta^2 \sec^2 \theta} = r^2 \left( \frac{\beta^2 + a^2 \tan^2 \theta}{a^2 \beta^2 \sec^2 \theta} \right)$$

and hence

$$(N4) \quad r = \left| \frac{ab \sec \theta}{\sqrt{\beta^2 + a^2 \tan^2 \theta}} \right| = \frac{ab |\sec \theta|}{\sqrt{|\beta^2 + a^2 \tan^2 \theta|}}.$$

We can now “nicely” write down an equation for  $\varepsilon$  in terms of  $a$  and  $\beta$ : since  $a = \frac{l}{1-\varepsilon^2}$  and  $l = \frac{\beta^2}{a}$ , we have that  $\varepsilon^2 = \frac{a^2 - \beta^2}{a^2}$ ; this becomes  $\varepsilon^2 = \frac{a^2 - b^2}{a^2}$  for an ellipse, and  $\varepsilon^2 = \frac{a^2 + b^2}{a^2}$  for a hyperbola. (This use of imaginary axes for the hyperbola thus wraps up the two different formulae for the eccentricity into a single formula, which is nice.) ■

Since we have only performed a translation, our curve is still in two disconnected branches. The equation for  $r$  is periodic with period  $2\pi$ , and is undefined precisely when  $b^2 - a^2 \tan^2 \theta \leq 0$ . The ‘boundaries’ of this area are thus the bounding lines of the hyperbola, and are the lines described by  $b^2 - a^2 \tan^2 \theta = 0$ , or  $\tan \theta = \pm \frac{b}{a}$ ; in other words,  $y = \pm \frac{b}{a}x$ .

We can now give the dimensions for the axes of the hyperbola. The  $x$ -intercepts of the hyperbola, as for the ellipse, are  $x = \pm a$ . Thus the four corners of the rectangle are  $(a, b)$ ,  $(-a, b)$ ,  $(a, -b)$ , and  $(-a, -b)$ . Thus the two side lengths of the rectangle, as claimed, are  $2a$  (in the  $x$ -direction) and  $2b$  (in the  $y$ -direction). [Note, in this situation we take  $b$  to be real, not imaginary.]

Finally, as  $x \rightarrow \infty$ , we need to show that the curve becomes arbitrarily close to the asymptotes. Indeed, we can easily show that  $\frac{dy}{dx} = \frac{xb^2}{ya^2}$ . Consider the portion of the hyperbola where  $x > 0$  and  $y > 0$ . Here,

$$y = b\sqrt{\frac{x^2}{a^2} - 1}$$

and so the equation of the tangent to the curve at  $(x_0, y_0)$  is

$$y = \frac{x_0 b^2}{y_0 a^2}(x - x_0) + y_0 = \frac{x_0 b}{a^2 \sqrt{\frac{x_0^2}{a^2} - 1}}x - \frac{x_0^2 b}{a^2 \sqrt{\frac{x_0^2}{a^2} - 1}} + b\sqrt{\frac{x_0^2}{a^2} - 1}.$$

The slope of the tangent line, as  $x_0 \rightarrow \infty$ , is

$$\frac{x_0 b}{a^2 \sqrt{\frac{x_0^2}{a^2} - 1}} = \frac{b}{a^2 \sqrt{\frac{1}{a^2} - \frac{1}{x_0^2}}} \rightarrow \frac{b}{a^2 \sqrt{\frac{1}{a^2} - 0}} = \frac{b}{a}.$$

Further, the  $y$ -intercept becomes

$$-\frac{x_0^2 b}{a^2 \sqrt{\frac{x_0^2}{a^2} - 1}} + b\sqrt{\frac{x_0^2}{a^2} - 1} = \frac{ba^2(\frac{x_0^2}{a^2} - 1) - x_0^2 b}{a^2 \sqrt{\frac{x_0^2}{a^2} - 1}} = \frac{-ba^2}{a^2 \sqrt{\frac{x_0^2}{a^2} - 1}} \rightarrow 0$$

when  $x_0 \rightarrow \infty$ .

Thus the tangent line of the curve approaches  $y = \frac{b}{a}x$  as  $x \rightarrow \infty$ , and hence the curve itself approaches this line. We can perform similar calculations for the various cases where  $x < 0$  or  $y < 0$  (or both).

For the parabola, since  $\varepsilon = 1$ , we obtain  $x^2 + y^2 = (l - x)^2 = l^2 - 2lx + x^2$ , and so  $y^2 = 2l(\frac{1}{2}l - x)$ . If we reflect in the line  $x = l/4$ , then we map

$$(x, y) \rightarrow (-(x - l/4) + l/4, y) = (l/2 - x, y)$$

and our equation becomes

$$y^2 = 2l \left( \frac{l}{2} - \frac{l}{2} + x \right) = 2lx.$$

We obtained the equation  $y^2 = 2l(\frac{1}{2}l - x)$  using the focus polar form, and so in that form the focus was  $(0, 0)$ . In doing our reflection, we mapped  $(0, 0) \rightarrow (l/2, 0)$ ; hence this is the location of the focus. In other words, if  $y^2 = 4ax$ , then  $2l = 4a$  and  $a = l/2$ ; so  $(a, 0)$  is the focus. The directrix of the original form was located at  $x = l/\varepsilon = l$ ; after the transformation, it is located at  $x = -l/2$ , or (if we write the equation as  $y^2 = 4ax$ ) it is located at  $x = -a$ . (These results suggest that  $y^2 = 4ax$  is the most natural form for the equation of the parabola.)

### Exercise 3: Parametric form.

Show that:

1. The ellipse  $x^2/a^2 + y^2/b^2 = 1$  is parameterised by  $(a \cos t, b \sin t)$  for  $0 \leq t < 2\pi$ .
2. The parabola  $y^2 = 2lx$  is parameterised by  $(2lt^2, 2lt)$ .
3. The hyperbola  $x^2/a^2 - y^2/b^2 = 1$  is parameterised by  $(a \sec t, b \tan t)$  for  $0 \leq t < 2\pi$ .

Illustrate these parameterisations with a suitable computer program (e.g. Geogebra, or your favourite programming language).

Consider the ellipse case. We need to show two things:

- I. That each point of the form  $(a \cos t, b \sin t)$  lies on the ellipse.
- II. That for each point  $(x, y)$  on the ellipse there exists some unique  $t$  lying in the range  $0 \leq t < 2\pi$  such that  $(x, y) = (a \cos t, b \sin t)$ .

Point I is easy:  $(a \cos t)^2/a^2 + (b \sin t)^2/b^2 = \cos^2 t + \sin^2 t = 1$ , so each such point is indeed on the ellipse.

Now, suppose  $(x, y)$  lies on the ellipse. Let us begin by finding all  $t$  such that  $a \cos t = x$ ; indeed,  $\cos t = x/a$ , and (by our earlier results) we know that  $|x| \leq |a|$  so there exists some  $t_0$  in the given range such that  $\cos t_0 = x/a$ ; further,  $2\pi - t_0$  is the only other point in the range which might satisfy this equation.

Let us now consider  $\sin t_0$  and  $\sin(2\pi - t_0)$ . We have  $x^2/a^2 + y^2/b^2 = 1$ , so  $\cos^2 t_0 + y^2/b^2 = 1$ . It follows that  $1 - \sin^2 t_0 + y^2/b^2 = 1$ , and hence that  $\sin^2 t_0 = y^2/b^2$ ; so  $\sin t_0 = \pm y/b$ .

Suppose that  $\sin t_0 = -y/b$ . Then  $\sin(2\pi - t_0) = -\sin(t_0)$  (by standard properties of the sine function), and so  $\sin(2\pi - t_0) = y/b$ ; thus  $y = b \sin(2\pi - t_0)$  and  $x = a \cos(2\pi - t_0)$ ,  $t = 2\pi - t_0$  is the only substitution such that both  $y = b \sin t$  and  $x = a \cos t$  work.

It remains to show that if  $\sin t_0 = y/b$  then  $\sin(2\pi - t_0) \neq y/b$  (for if both held, then we wouldn't have a unique value for  $t$ : both  $t_0$  and  $2\pi - t_0$  would work). But by the same reasoning as above,  $\sin t_0 = y/b$  implies  $\sin(2\pi - t_0) = -y/b \neq y/b$ ; so if  $\sin t_0 = y/b$  then the substitution  $t = t_0$  is the unique parameter giving the point  $(x, y)$ .

The same process works for both the hyperbola and the ellipse.

### Exercise 4: Focii of rectangular conics.

Given the equation

$$\frac{x^2}{a^2} \pm \frac{y^2}{b^2} = 1,$$

compute the coordinates of the focus, equation of the directrix, and eccentricity of the conic. Hence show that ellipses and hyperbolae have two focii and two directrices each. Where is the directrix of a circle?

Show that the following two properties can be used as alternative definitions for the ellipse and hyperbola:

- AP1. Show that the ellipse with focii  $O_1$  and  $O_2$  is the locus of all points  $P$  such that  $d(O_1, P) + d(P, O_2) = R$  for some constant  $R$ . Give  $R$  in terms of  $a$  and  $b$ .
- AP2. Show that the hyperbola with focii  $O_1$  and  $O_2$  is the locus of all points  $P$  such that  $d(O_1, P) - d(P, O_2) = R$  for some constant  $R$ . Give  $R$  in terms of  $a$  and  $b$ .

As an application of this definition, we will derive the 'reflection property' of the ellipse.

- I. Suppose  $O_1$  and  $O_2$  are on the same side of a line  $\ell$ . Show that the shortest path from  $O_1$  to  $O_2$  which touches the line  $\ell$  is the broken line  $O_1XO_2$ , where  $X$  is on  $\ell$  and the angles between  $O_1X$  and  $\ell$  and between  $XO_2$  and  $\ell$  are equal. (Hint: you can do this with calculus, but that would be like killing a fly with a sledgehammer.)
- II. Show that, if  $O_1$  and  $O_2$  are two foci of an ellipse and  $X$  is any point on the ellipse, then the broken line  $O_1XO_2$  makes equal angles with the tangent line of the ellipse at  $X$ . (Hint: show that this broken line is the shortest path from  $O_1$  to  $O_2$  that touches the tangent line at  $X$ .)
- III. Thus, given the law of reflection for waves, show that if a light source is placed at  $O_1$  then every ray from the source will arrive at  $O_2$  at precisely the same time.
- IV. Derive some result of this kind for parabolas by treating a parabola as an ellipse with one focus ‘at infinity’. Suggest an application of this property related to, say, torches.

We saw in exercise 2 that  $l = \frac{\beta^2}{a}$  and  $\varepsilon^2 = \frac{a^2 - \beta^2}{a^2}$  (where, again,  $\beta = b$  for an ellipse and  $\beta = ib$  for a hyperbola). When origin is at the focus, the directrix was  $x = l/\varepsilon$ ; when we put the equation into the normal rectangular form, we performed the transformation  $(x, y) \mapsto (x - \varepsilon a, y)$  and so the focus is now at  $(-\varepsilon a, 0)$ ; if  $c = \varepsilon a$  then  $c^2 = \varepsilon^2 a^2 = a^2 - \beta^2$ ; thus the foci lie at  $(\pm c, 0) = (\pm(a^2 - \beta^2)^{1/2}, 0)$ . The directrix is now at

$$x = l/\varepsilon - \varepsilon a = \frac{\beta^2}{a\varepsilon} - \varepsilon a = \frac{\beta^2 - \varepsilon^2 a^2}{\varepsilon a} = \frac{2\beta^2 - a^2}{\varepsilon a}$$

$$x^2 = \frac{(2\beta^2 - a^2)^2}{a^2 - \beta^2}.$$

For a circle,  $\beta = a$ . Hence the directrix will be “at infinity” in the sense that it is undefined but that  $x \rightarrow \infty$  in the above calculation as  $\beta \rightarrow a$ .

(Note that we don’t actually need to do any calculations to show that ellipses and hyperbolae must have two foci and two directrices, because it follows immediately from the fact that the figures are symmetric about the  $y$ -axis and so the reflections of the initial focus and directrix from the definition must also generate the same conic.)

We will now prove the ‘string-and-stakes’ definitions for the ellipse.<sup>3</sup>

Suppose  $O_1$  and  $O_2$  are two points, and that  $R$  is some positive number. Let  $\mathcal{F}$  be the locus of all points  $P$  satisfying the relation  $d(P, O_1) + d(P, O_2) = R$ . We want to do some coordinate geometry, so we need to pick a coordinate system; we will choose the origin to be the midpoint  $O = m(O_1, O_2)$  and then, setting  $c = d(O_1, O) = d(O_2, O)$ , we will place  $O_1$  and  $O_2$  on the  $x$ -axis at  $O_1 = (-c, 0)$  and  $O_2 = (c, 0)$ .

Let  $P = (x, y)$  satisfy the given relation; then  $R = \sqrt{(x+c)^2 + y^2} + \sqrt{(x-c)^2 + y^2}$ , so

$$\begin{aligned} (R - \sqrt{(x-c)^2 + y^2})^2 &= x^2 + 2xc + c^2 + y^2 \\ R^2 - 2R\sqrt{(x-c)^2 + y^2} &= 4xc \\ (x-c)^2 + y^2 &= \left( \frac{R^2 - 4xc}{2R} \right)^2 \\ x^2 - 2cx + c^2 + y^2 &= \frac{R^4 - 8cR^2x + 16c^2x^2}{4R^2} \\ x^2 + c^2 + y^2 &= \frac{R^2}{4} + \frac{4c^2}{R^2}x^2 \\ \frac{1 - \frac{4c^2}{R^2}}{\frac{R^2}{4} - c^2}x^2 + \frac{1}{\frac{R^2}{4} - c^2}y^2 &= 1. \end{aligned}$$

So every such point  $P$  lies on the ellipse with  $a^2 = \frac{\frac{R^2}{4} - c^2}{1 - \frac{4c^2}{R^2}}$  and  $b^2 = \frac{R^2}{4} - c^2$ .

Further, suppose  $P = (x, y)$  lies on the ellipse. We need to show that  $R = d(O_1, P) + d(O_2, P)$ ; this can be done by simply running the above calculation backwards.

A similar computation can be done for the hyperbola.

- I. There is a standard trick here: form  $O'_2$  by reflecting  $O_2$  across  $\ell$ ; then  $|O_2X| = |O'_2X|$  for every  $X$  on  $\ell$ . Let us pick such an  $X$  by taking the intersection of  $O_1O_2$  with  $\ell$ ; then for any other point  $Y$  on  $\ell$ ,

<sup>3</sup>For an explanation of the name ‘string-and-stakes’, see [https://www.youtube.com/watch?v=Et30dzEGX\\_w](https://www.youtube.com/watch?v=Et30dzEGX_w).

$|O_1X| + |O_2'X| = |O_1O_2'| \leq |O_1Y| + |YO_2'|$ . Thus  $X$  is the required point. To show the given angles are equal, look at the triangles formed by  $O_2XO_2'$ ; they are congruent by construction, and hence the two angles at  $X$  are equal; then the angle between  $O_1X$  and  $\ell$  is opposite and thus equal to one of these angles.

- II. To show this result, I will prove a stronger proposition and then deduce the hint as a special case. Consider the given ellipse; suppose it is the locus of all points  $X$  such that  $d(O_1, X) + d(O_2, X) = R$ . Let  $P$  be any point outside the ellipse; I claim that  $d(O_1, P) + d(O_2, P) > R$ . Pick  $Q$  to be the intersection between the ellipse and the angular bisector of  $O_1XO_2$ ; then  $d(O_1, Q) + d(O_2, Q) = R$ . On the other hand,  $d(O_1, P) \geq d(O_1, Q) + d(Q, P)$ ; similarly,  $d(O_2, P) \geq d(O_2, Q) + d(Q, P)$ . Thus  $d(O_1, P) + d(O_2, P) \geq d(O_1, Q) + 2d(Q, P) + d(O_2, Q) = R + 2d(Q, P) \geq R$  with equality if and only if  $P = Q$ , which is not the case.<sup>4</sup>

Now, let  $X$  be any point on the ellipse. Then every point on the tangent line to the ellipse at  $X$ , except  $X$  itself, lies outside the ellipse. Hence for all such points  $Y$ ,  $d(O_1, Y) + d(O_2, Y) \geq R$ . Thus the minimum distance between  $O_1$  and  $O_2$  via a point on the tangent line occurs when we travel via  $X$ , as this is the only point for which we can attain equality.

By result I it follows immediately that the two angles are equal.

- III. The reflection law for waves states that a wave hitting a surface will reflect at an equal angle; thus light rays from  $O_1$  will (by II) pass through  $O_2$ . Further, the distance all such rays travel is  $R$ ; hence all rays from  $O_1$  will reach  $O_2$  in equal time despite taking different paths.
- IV. For a parabola, all waves from the focus  $O$  will reflect ‘towards infinity’ — they will reflect away from the vertex, parallel to the axis of the parabola.

<sup>4</sup>Exercise: show that if  $P$  lies within the ellipse, then  $d(O_1, P) + d(O_2, P) < R$ .

### Exercise 5: Further thoughts on this argument.

You are asked to think critically about the above argument (so reread it and check the computations) and to extend it (so not only must you read it, but understand it).

- I. Clearly  $y = x^2$  cannot be written in the canonical form. Where does the proof above fall down for a parabola?
- II. What happens if our ellipse is a circle?
- III. We have now classified the quadratic equations in two variables corresponding to hyperbolae and ellipses ( $px^2 \pm qy^2 = 1$ ) and parabolae ( $y^2 = kx^2$ ). What other forms can the graph of such a quadratic equation take? (Hint: you should be able to find three other kinds, and show that every quadratic equation is of one of the six kinds.)

- I. The issue is that we cannot complete the square in  $x$  — there is no square.
